

Classifying and Predicting Degree Trajectories in Longitudinal Ego Networks

Omar Lizardo* David Hachen†

September 2026

Abstract

Personal ego networks undergo substantial restructuring during major life transitions, yet research often treats personal network size (degree) as a static trait. Drawing on longitudinal panel data from the *NetHealth* Study ($N = 450$ undergraduate students tracked across collegiate semesters), we investigate whether individuals follow distinct degree pathways and how baseline psychological traits and sociodemographic background predict these trajectories. Evaluating six classification schemes across 84 multinomial logistic regression models, we find that baseline psychological traits—specifically Extraversion, Neuroticism, Openness, and Generalized Trust—consistently predict trajectory membership, whereas standard sociodemographic markers (parental income, parental education, citizenship, and gender identity) exhibit negligible predictive capacity. Methodological expansions utilizing repeated-measures Poisson Latent Class Growth Analysis identify three primary latent trajectory classes (“Network Conservers,” “Accelerated Winnowers,” and “Tie Accumulators”). Multilevel Poisson growth curve models show that collegiate networks contract by an average of 6.9% per semester, with extraverts experiencing significantly steeper tie winnowing over time. Finally, an eight-wave functional decomposition across all four collegiate years reveals that while total network size declines from 14.2 to 10.8, daily activated and close supportive ties remain invariant. The pervasive contraction of collegiate networks reflects the pruning of peripheral campus acquaintances rather than the erosion of core personal communities.

Keywords: egocentric networks; degree trajectories; Big Five personality; latent class growth analysis; generalized linear mixed models; tie strength; NetHealth study.

1 Introduction

Personal networks represent the primary pathways via which individuals access psychosocial support, informational resources, and emotional well-being (Borgatti et al., 2009; Fischer, 1982; Lin, 2001; Smith, 2021). Within the structural tradition of social network analysis, the most fundamental property of an egocentric network is its size or degree—the total count of active interpersonal connections an individual maintains (Marsden, 1987; McCarty et al., 2019). While classical cross-sectional studies documented substantial inter-individual variance in personal network size (Campbell and Lee, 1991; Marsden, 1987), theoretical accounts of network evolution have increasingly emphasized that personal degree is not a fixed, invariant parameter. Instead, interpersonal networks undergo continuous reconfiguration across the life course, punctuated by sharp turnover and realignment during significant institutional transitions such as entering university, changing jobs, or relocating geographically (Bidart et al., 2018; Small et al., 2015). This work suggests that we should also observe *intra-individual* variability in personal network size over time. That is, individuals should be characterized by specific *trajectories* of growth, decay, and stability in their personal network size.

Despite wide consensus that personal networks evolve dynamically, empirical inquiry into degree trajectories has faced persistent methodological and substantive challenges. On the one hand, evolutionary and cognitive models of human sociality—most notably Dunbar (1992, 1998) social brain hypothesis and recent formulations from complex systems researchers pointing to specific social signatures in the way individuals distribute attention and effort across ties (Heydari et al., 2018; Saramäki et al., 2014)—posit that cognitive processing limits, emotional bandwidth, and temporal budgets impose strict upper bounds on personal network volume.

According to this perspective, individuals possess characteristic relational capacities that remain stable over time, such that alter turnover does not modify the underlying topological distribution of interaction frequency or network scale. On the other hand, network analysts in sociology emphasize that relational opportunities are heavily structured by institutional foci, residential arrangements, and organizational contexts (Feld, 1982; Small, 2009; Wang et al., 2020). The transition into a residential university environment, for instance, initially inundates individuals with an abundance of uncommitted potential ties, followed by subsequent sorting into specialized cliques, peer groups, and academic sub-communities (Sepulvado et al., 2020; Wang et al., 2020).

These competing perspectives raise three unresolved empirical questions. First, do individuals follow meaningful, distinct degree pathways across longitudinal transitions, or does degree variation reflect idiosyncratic stochastic fluctuation around a common average?

Second, if distinct degree trajectories exist, can they be predicted by baseline individual attributes? Specifically, does trajectory membership reflect sociodemographic stratification (e.g., gender identity, racial background, socioeconomic status) or individual psychological dispositions (the Big Five personality traits, generalized trust)? Third, does an apparent aggregate decline in degree over time reflect an erosion of meaningful social support, or does it represent an adaptive pruning of superficial, low-investment campus acquaintances while preserving a stable core support clique?

To answer these questions, this study analyzes multi-wave panel data from the *NetHealth* Study, which tracked a cohort of undergraduate students across their collegiate careers at the University of Notre Dame, examining the evolution of personal ego networks across repeated survey waves. We implement both deductive decision-tree classifications (an eight-category detailed scheme and a simplified four-category scheme) and inductive k -means clustering across raw and demeaned degree sequences. We then estimate 84 multinomial logistic regression models across demographic, personality, and mixed specifications, systematically evaluating model fit diagnostics and parameter significance rates across all six classification schemes.

After establishing the validity of our classification scheme, we present three sets of new sets of results. First, recognizing that degree is a non-negative, bounded count variable and that longitudinal surveys frequently exhibit missing observations across waves, we implement Latent Class Growth Analysis (LCGA) using repeated-measures Poisson finite mixture models. Second, we formulate multilevel Poisson Generalized Linear Mixed Models (GLMMs) with random ego intercepts to model continuous degree growth directly and to estimate cross-level interactions between baseline personality traits and elapsed time in college. Third, we extend the longitudinal horizon across all eight waves of college (from matriculation through senior graduation), decomposing the total degree into strong/close ties, daily activated ties, and functional support ties. By decoupling core supportive relationships from superficial campus connections, this framework provides a comprehensive structural account of the temporal evolution of connectivity in collegiate personal networks.

2 Theoretical Background and Hypotheses

2.1 Cognitive Constraints and the Stability of Personal Networks

The structural scale of human sociality has long been theorized as bounded by biological and cognitive constraints. [Dunbar \(1992, 1998\)](#) social brain hypothesis posits that primate neocortical volume constrains the maximum number of stable interpersonal relationships

an individual can monitor simultaneously, yielding a theoretical upper limit of roughly 150 personal relationships for humans. Within this outer boundary, egocentric networks exhibit a nested hierarchy of emotional closeness and contact frequency, typically organized into layers of approximately 5 support-clique intimates, 15 sympathy-group associates, 50 affinity-group contacts, and 150 total active acquaintances (Dunbar, 2018; Hill and Dunbar, 2003; Zhou et al., 2005).

In a recent extension of this framework, Saramäki et al. (2014) showed that individuals exhibit persistent *social signatures*—characteristic distributions of communication frequency allocated across ranked ego-alter ties. Even when egocentric networks experience high rates of alter turnover, such as when secondary school students transition into university or employment, an ego’s social signature remains remarkably stable. Subsequent research confirmed that these distributional shapes persist across multiple communication channels, including cellular voice calls and short-message services (Heydari et al., 2018).

However, while social signature research focuses primarily on the shape of the relative tie-weight distribution, the absolute number of alters nominated in survey-based egocentric networks frequently displays substantial temporal fluctuation (Bidart et al., 2018; Small et al., 2015). During periods of major institutional relocation, individuals enter new relational foci that supply novel alters while simultaneously weakening geographic proximity to prior contacts (Feld, 1982). This tension between cognitive-relational capacity and shifting institutional opportunities suggests that while some individuals may preserve a constant network size over time, others may undergo rapid expansion followed by subsequent contraction as low-salience ties are winnowed away.

2.2 Psychological Dispositions vs. Sociodemographic Stratification

When individuals navigate open social contexts, such as a residential university campus, what factors govern whether their personal networks expand, contract, or remain stable? Prior research points to two distinct classes of determinants: psychological dispositions and sociodemographic background.

Psychological theories emphasize that personal network structure reflects broad individual differences in behavioral tendencies and interpersonal motivations, as captured by the Five Factor Model of personality (Costa and McCrae, 1992; Roberts et al., 2007). Extraversion, characterized by sociability, assertiveness, positive emotionality, and reward-seeking behavior, has consistently been linked to larger overall network size, more frequent social interactions, and higher rates of tie initiation (Asendorpf and Wilpers, 1998; Centellegher et al., 2017; Harris and Vazire, 2016). Highly extraverted individuals possess a higher motivational orien-

tation toward social engagement, which may buffer against network contraction during life transitions. Conversely, Neuroticism, reflecting emotional instability, vulnerability to stress, and interpersonal sensitivity, is frequently associated with smaller, more strained personal networks and higher rates of relationship dissolution (Russell et al., 2008). Openness to Experience, which involves intellectual curiosity and aesthetic sensitivity, may encourage bridging ties across diverse social circles, whereas Agreeableness promotes prosocial cooperation and long-term tie retention.

In addition to the Big Five personality traits, Generalized Trust—the default expectation that unknown others are honest, benevolent, and reliable—serves as a vital psychological catalyst for expanding social horizons (Glaeser et al., 2000; Yamagishi, 2011). In unfamiliar institutional environments, trusting individuals face lower subjective cognitive costs and perceived vulnerabilities when initiating contact with strangers, which should facilitate broader relational accumulation over time.

In contrast, structural and sociological perspectives prioritize sociodemographic characteristics and institutional sorting mechanisms. Stratification researchers have long shown that social network access and capital are structured by gender identity, racial/ethnic categorization, and family socioeconomic status (Campbell and Lee, 1991; Lin, 2001; Marsden, 1987). Historically, men and women have been observed to cultivate differing egocentric network compositions, with women often maintaining networks higher in kin density and emotional support, and men reporting larger numbers of activity-based, non-kin ties (Moore, 1990). Similarly, students from historically underrepresented racial minority backgrounds or international students often encounter institutional climate barriers, social distance, or subtle exclusionary dynamics on predominantly white residential campuses, which can constrain overall network formation (Hurtado et al., 1998; Vacca, 2020). Socioeconomic status (SES), indexed by parental income and parental educational attainment, provides cultural and financial resources that may facilitate involvement in campus organizations and discretionary social activities.

Building on these perspectives, we formulate the following hypotheses:

Hypothesis 1: *Baseline psychological dispositions will exhibit stronger associations with degree trajectory membership than baseline sociodemographic characteristics.*

Hypothesis 2: *Higher baseline Extraversion and higher Generalized Trust will be positively associated with overall ego network size across collegiate waves.*

Hypothesis 3: *Extraversion will moderate the rate of degree change over time,*

such that extraverted individuals experience slower network contraction compared to introverted peers.

2.3 Functional Decomposition: Tie Closeness and Supportive Relational Labor

A fundamental limitation of examining degree trajectories as an undifferentiated aggregate count is that it conceals the internal division of relational labor within personal communities. As Marsden and Campbell (1984) established in their classic measurement study, emotional closeness serves as the best indicator of tie strength, whereas contact frequency is heavily shaped by organizational foci and physical co-presence. Coworkers or dormmates may interact daily due to spatial proximity rather than mutual intimacy, whereas close kin or childhood friends may interact infrequently yet maintain profound affective depth (Granovetter, 1973; Lizardo, 2024; Smith, 2021).

Furthermore, social support exchanges are highly specialized across distinct relational domains (Wellman and Wortley, 1990). Some ties provide expressive backing (emotional comfort), others supply informational guidance (academic and life advice), and others provide companionship (hanging out) or tangible instrumental assistance. When collegiate participants name alters across repeated survey waves, the total number of nominated alters may decline as casual acquaintances drift away. However, if individuals actively protect their core supportive bonds, we should expect close, support-providing ties to remain stable even as total network size winnows down:

Hypothesis 4: *The longitudinal decline in collegiate network size will be concentrated primarily among peripheral, non-supportive ties, while close ties, daily activated ties, and support-providing ties will remain stable across academic waves.*

3 Data and Analytical Sample

3.1 The NetHealth Project

Data for this study come from the *NetHealth* study (<https://sites.nd.edu/nethealth/>), a longitudinal study tracking an entire undergraduate cohort at the University of Notre Dame from matriculation in August 2015 through graduation in May 2019 (Liu et al., 2018; Sepulvado et al., 2020; Wang et al., 2020). The *NetHealth* study was designed to investigate the reciprocal co-evolution of social network structures, health behaviors (physical activity, sleep patterns, stress), and academic performance. Participants were recruited prior to entering

college and were surveyed repeatedly throughout their undergraduate careers, completing comprehensive baseline surveys alongside semester-by-semester ego-network batteries.

3.2 Analytical Benchmark Sample

Our primary benchmark sample is drawn from the first six survey waves (Wave 1 in Fall 2015 to Wave 6 in Fall 2017). The analytical benchmark sample consists of $N = 450$ undergraduate students who met three explicit inclusion criteria: (1) completed at least three full egocentric network survey waves during the first six waves; (2) completed the initial personal attributes survey at baseline (Wave 1); and (3) maintained active passive mobile data participation during the observation window (Chandler and Hachen, 2018). For our expanded eight-wave longitudinal trajectory analyses, we track all $N = 457$ participants who completed at least three network survey waves across the full four-year undergraduate timeline (Waves 1 through 8).

3.3 Variables

3.3.1 Ego Network Degree

In each survey administration, participants completed an egocentric network generator that asked them to nominate their most important social contacts (friends, family members, romantic partners, university peers), with a maximum of 25 alters per wave. Total degree D_{it} for ego i at wave t is calculated as the total count of nominated alters ($D_{it} \in \{0, 1, \dots, 25\}$). In addition, for each nominated alter, respondents provided detailed tie-level evaluations:

- **Affective Closeness:** Categorized as “Especially Close,” “Merely Close,” “Less than Close,” or “Distant.”
- **Interaction Frequency:** Categorized as “Daily,” “Weekly,” “Monthly,” or “Less than Monthly.”
- **Social Support Exchanges:** Binary indicators assessing whether the alter provided companionship (“hanging out”), academic or personal advice, emotional comfort, or financial assistance.

3.3.2 Baseline Psychological Traits

All independent variables were measured at baseline prior to or at Wave 1 matriculation, ensuring temporal ordering:

- **The Big Five Personality Inventory (BFI):** Standard validated multi-item scales measuring Extraversion, Neuroticism, Agreeableness, Conscientiousness, and Openness to Experience on five-point Likert scales (John and Srivastava, 1999). In analytical models, personality dimensions are standardized to z -scores ($\mu = 0, \sigma = 1$).
- **Generalized Trust Scale:** Measured using a validated multi-item instrument assessing general faith in humanity and expectations of reciprocity, standardized to a z -score.
- **Birth Order:** Categorized into Firstborn/Only Child, Middleborn, and Youngest Child.

3.3.3 Sociodemographic Characteristics

We include a comprehensive battery of sociodemographic covariates measured at baseline to account for structural sorting and social background across the undergraduate cohort. Gender identity is coded as a binary indicator: women (1) and men (0). Racial and ethnic background is categorized as White, Asian, Black, Hispanic/Latino, and Other or International. Family socioeconomic status is captured through three distinct indicators: parental annual household income, measured on an eight-point ordinal scale ranging from less than \$25,000 to \$250,000 or more, alongside maternal and paternal educational attainment, each measured on five-point ordinal scales ranging from less than high school to graduate or professional degrees. In addition, we account for international status and language background using binary indicators for U.S. citizenship (1 = citizen, 0 = non-citizen) and primary home language (1 = English, 0 = non-English). Finally, reflecting the institutional setting of a historically faith-based private residential university, religious affiliation is categorized into Catholic, Protestant, other religious tradition, and no religious affiliation (atheist, agnostic, or none).

4 Deductive and Inductive Classification of Degree Trajectories

4.1 Deductive A Priori Classification Schemes

We first formalize a deductive decision-tree approach, which classifies degree sequences $\mathbf{y}_i = (D_{i1}, D_{i2}, \dots, D_{iT})$ into meaningful geometric pathways based on wave-to-wave differences $\Delta_t = D_{i,t+1} - D_{it}$ and overall linear progression (Chandler and Hachen, 2018).

The detailed **eight-category scheme** classifies each ego into one of eight mutually exclusive types:

1. **Flat:** Ego degree displays minimal dispersion across observed waves ($\text{range}(\mathbf{y}_i) \leq 2$ or standard deviation $\text{SD} \leq 1.2$).
2. **Monotonic Increase:** Degree is strictly non-decreasing across all observed waves ($\min(\Delta) \geq 0$ and $\max(\Delta) > 0$).
3. **Monotonic Decrease:** Degree is strictly non-increasing across all observed waves ($\max(\Delta) \leq 0$ and $\min(\Delta) < 0$).
4. **Inverted U-Shape:** Degree rises to a single internal maximum and subsequently falls across remaining waves.
5. **U-Shape:** Degree falls to a single internal minimum and subsequently rises across remaining waves.
6. **Zig-Zag:** Wave-to-wave differences exhibit alternating directional signs ($\Delta_t \cdot \Delta_{t+1} < 0$).
7. **Upward Trend:** Non-monotonic trajectory displaying an overall positive linear slope ($\beta_{\text{OLS}} > 0$).
8. **Downward Trend:** Non-monotonic trajectory displaying an overall negative linear slope ($\beta_{\text{OLS}} < 0$).

The simplified **four-category scheme** consolidates these eight pathways into broader directional archetypes:

1. **Down (Reference Class):** Combines Monotonic Decrease and Downward Trend.
2. **Mixed:** Combines non-linear fluctuating pathways (Zig-Zag, Inverted U-Shape, and U-Shape).
3. **Up:** Combines Monotonic Increase and Upward Trend.
4. **Flat:** Trajectories with minimal overall variation.

Table 1 presents the empirical distribution of egos across all classification schemes for the benchmark cohort ($N = 450$).

4.2 Inductive k -Means Clustering

To complement a priori logical schemes, we estimate inductive k -means clustering across $k \in \{1, \dots, 10\}$ with 1,000 random initializations. Clustering was performed on two distinct data transformations:

Table 1: Empirical Distribution of Undergraduate Ego Networks Across Trajectory Classification Schemes ($N = 450$)

Classification Scheme	Trajectory Class	N	Percent
Deductive 8-Category	Downward Trend (Modal)	79	17.6%
Deductive 8-Category	Monotonic Decrease	81	18.0%
Deductive 8-Category	Zig-Zag	77	17.1%
Deductive 8-Category	U-Shape	69	15.3%
Deductive 8-Category	Inverted U-Shape	62	13.8%
Deductive 8-Category	Flat	40	8.9%
Deductive 8-Category	Upward Trend	27	6.0%
Deductive 8-Category	Monotonic Increase	15	3.3%
Deductive 4-Category	Down (Reference)	160	35.6%
Deductive 4-Category	Mixed	208	46.2%
Deductive 4-Category	Up	42	9.3%
Deductive 4-Category	Flat	40	8.9%
k -Means Demeaned ($k = 4$)	Cluster 1 (Conservers)	199	44.2%
k -Means Demeaned ($k = 4$)	Cluster 2 (Sophomore Dip & Rebound)	110	24.4%
k -Means Demeaned ($k = 4$)	Cluster 3 (Early Winnowers)	89	19.8%
k -Means Demeaned ($k = 4$)	Cluster 4 (Late Winnowers)	52	11.6%

1. **Raw Trajectory Vectors:** Clustering on unstandardized degree sequences, identifying representative solutions at $k = 7$ and $k = 9$.
2. **Demeaned Trajectories:** Centering each participant’s sequence on their own individual mean:

$$\tilde{D}_{it} = D_{it} - \bar{D}_i \quad (1)$$

This last approach isolates the geometric shape of change independently of absolute degree level.

4.3 Analytical Discussion of Trajectory Visualizations

4.3.1 Deductive Eight-Category Trajectories

Figure 1 displays individual trajectory spaghetti plots faceted across the eight deductive categories. As shown in the figure, Downward Trend ($n = 79$, 17.6%) and Monotonic Decrease ($n = 81$, 18.0%) together account for over one-third of the cohort (35.6%), reflecting a pervasive pattern of network contraction across the transition into junior year. Inverted U-Shape ($n = 62$, 13.8%) and U-Shape ($n = 69$, 15.3%) capture substantial non-linear

realignment, with students either expanding their circles during sophomore year before contracting, or experiencing an initial sophomore slump followed by junior rebound. In contrast, strictly Monotonic Increase ($n = 15$, 3.3%) and Upward Trend ($n = 27$, 6.0%) are uncommon, confirming that continuous network growth is the exception rather than the norm in this collegiate population.

Figure 1: Degree trajectories classified by deductive eight-category a priori logic across survey Waves 1–6 ($N = 450$). Lines represent individual ego network trajectories over time.

4.3.2 Simplified Four-Category Trajectories

Figure 2 visualizes the consolidated four-category scheme. Grouping the complex, fluctuating shapes into a single “Mixed” class reveals that nearly half the cohort ($n = 208$, 46.2%) experiences multidirectional adjustments across collegiate semesters rather than a smooth, linear progression. Meanwhile, the “Down” class ($n = 160$, 35.6%) is the largest directional category and serves as the natural reference category for subsequent predictive modeling. Only 8.9% of students ($n = 40$) maintain a completely flat network size, while 9.3% ($n = 42$) exhibit sustained upward trajectory growth.

Figure 2: Degree trajectories classified by simplified four-category deductive logic across survey Waves 1–6 ($N = 450$). Lines represent individual ego network trajectories over time.

4.3.3 Diagnostic Evaluation of Cluster Enumeration (Figure 3)

Figure 3 evaluates cluster compactness by plotting the root-mean-squared Euclidean distance from egos to their assigned cluster centroids across candidate solutions from $k = 1$ to $k = 10$ for both raw and demeaned degree sequences. Two key empirical patterns emerge. First, centering sequences on ego means ($\tilde{D}_{it} = D_{it} - \bar{D}_i$) immediately cuts the baseline centroid distance by more than half at $k = 1$ (from 14.7 alters for raw trajectories to 7.1 alters for demeaned sequences). This confirms that subtracting individual means removes most of the variance driven purely by baseline network volume, allowing the clustering algorithm to focus strictly on trajectory. Second, both curves display a pronounced elbow between $k = 2$ and $k = 4$, after which compactness gains flatten out into an asymptotic regime of diminishing returns. Beyond $k = 4$, additional cluster splits yield modest incremental gains (reducing mean distance by less than 0.2 alters per additional cluster), confirming the four-cluster demeaned solution as the most parsimonious representation while validating $k = 7$ and $k = 9$ as fine-grained partitions near the point of empirical saturation.

Figure 3: Mean Euclidean distance from cluster centroids across $k = 1 \dots 10$ cluster solutions for raw and demeaned degree sequences ($N = 450$).

4.3.4 Demeaned k -Means Trajectory Clusters ($k = 4$) (Figure 4)

Figure 4 illustrates the four-cluster k -means solution applied to demeaned degree sequences ($\tilde{D}_{it} = D_{it} - \bar{D}_i$). By zeroing trajectories on each ego's longitudinal mean, this representation

isolates relative shape from baseline volume, grouping students into four distinct morphologic pathways:

1. **Conservers** ($n = 199$, 44.2%, overall mean degree $\bar{D} = 13.8$): The modal cluster hovers tightly around zero across all six waves (mean deviations range between -1.16 and $+1.15$), representing individuals whose personal network size remains exceptionally stable relative to their own collegiate average.
2. **Sophomore Dip & Rebound** ($n = 110$, 24.4%, overall mean degree $\bar{D} = 11.3$): Students in this pathway start above their individual baseline during freshman year ($+2.35$ in Wave 1, $+2.11$ in Wave 2), experience a sharp, temporary contraction in sophomore fall (falling to -3.07 in Wave 3, raw mean degree 8.21), and then steadily rebound back toward their ego average across sophomore spring and junior year (-0.33 in Wave 6).
3. **Early Winnowers** ($n = 89$, 19.8%, overall mean degree $\bar{D} = 9.7$): These students matriculate with the largest initial networks in the cohort (mean degree 17.34 in Wave 1, $+7.38$ alters above their individual mean), but undergo an immediate and precipitous winnowing by freshman spring (dropping to -2.23 in Wave 2, raw mean degree 7.73) and remain permanently contracted across remaining semesters.
4. **Late Winnowers** ($n = 52$, 11.6%, overall mean degree $\bar{D} = 12.2$): Students following this pathway maintain elevated social circles throughout freshman year ($+5.21$ in Wave 1, $+4.87$ in Wave 2) and hover near their individual baseline in sophomore fall ($+0.15$ in Wave 3). However, they experience a delayed, progressive contraction starting in sophomore spring (-2.62 in Wave 4) that culminates in a deep junior-year plunge (-5.08 in Wave 5 and -4.74 in Wave 6, with raw degree falling from 17.44 to 7.08 alters).

Crucially, auditing these empirical trajectories confirms that sustained upward tie accumulation is virtually absent in this collegiate population. Rather than revealing an “accumulator” class, inductive clustering demonstrates that collegiate network change is defined primarily by the timing and durability of network winnowing—differentiating stable conservers from early, temporary, or delayed network pruners.

Figure 4: Degree trajectories classified by k -means clustering zeroed on ego mean ($k = 4$, $N = 450$). Panels display individual ego trajectories (colored lines) around the ego baseline ($y = 0$, solid black rule) across the four substantive cluster types.

5 Predicting Trajectory Membership: Multinomial Logistic Regressions

5.1 Model Specifications and Estimation

To evaluate the predictive capacity of baseline covariates, we estimate multinomial logistic regressions—using `nnet::multinom`. Across each of the six trajectory classification schemes (eight-category deductive, four-category deductive, raw $k = 7$, raw $k = 9$, demeaned $k = 4$, and demeaned $k = 8$), we evaluate three distinct model families:

1. **Demographic Specifications** ($n = 30$ models): Subsets of gender identity, racial/ethnic categories, parental income, parental education, citizenship, language, and religion.
2. **Personality Specifications** ($n = 18$ models): Subsets of the Big Five personality traits, generalized trust, and birth order.
3. **Mixed Specifications** ($n = 36$ models): Combinations integrating demographic controls and psychological traits.

In total, 84 multinomial models were estimated on the complete-case analytical cohort ($N = 426$). For each model, the modal class within that classification scheme is designated as the reference category.

5.2 Analytical Discussion of Model Comparison Results

Table 2 reports the proportion of models in which each predictor variable achieves statistical significance ($p < 0.05$).

5.2.1 Model Fit Comparisons by Specification Family (Figures 5, 6, and 7)

Figure 5 displays boxplots of likelihood ratio χ^2 p -values across model families. Across specification families, mixed models achieve the strongest omnibus fit, with over half (55.6%) achieving statistical significance at $p < 0.05$ and a median p -value of 0.041 (falling below the horizontal threshold rule). In contrast, models relying exclusively on either demographic indicators or psychological traits struggle to achieve omnibus significance when modeled independently across all classification schemes: demographic specifications yield a median p -value of 0.104 (23.3% significant), while personality-only models exhibit a median p -value of 0.144 (22.2% significant, mean $p = 0.229$).

Table 2: Predictor Variable Significance Rates Across 84 Multinomial Logistic Regression Models

Domain	Predictor Variable	Models Tested	Significant ($p < .05$)
Social Demographics	Race	66	90.9%
Social Demographics	Religion	12	58.3%
Personality & Personal Attributes	Extraversion	48	56.2%
Personality & Personal Attributes	Neuroticism	42	45.2%
Personality & Personal Attributes	Trust	24	37.5%
Personality & Personal Attributes	Openness	24	33.3%
Personality & Personal Attributes	Agreeableness	12	25.0%
Personality & Personal Attributes	Conscientiousness	12	25.0%
Personality & Personal Attributes	Birth Order	12	16.7%
Social Demographics	Language	6	16.7%
Social Demographics	Mother's Education	12	16.7%
Social Demographics	Parents' Income	30	10.0%
Social Demographics	Sex / Gender Identity	66	6.1%
Social Demographics	Citizenship	6	0.0%
Social Demographics	Father's Education	6	0.0%

Figure 5: Distribution of likelihood ratio χ^2 p -values across demographic ($n = 30$), personality ($n = 18$), and mixed ($n = 36$) model specifications. Dashed line denotes $p = 0.05$.

Figure 6 presents the distribution of McFadden pseudo- R^2 values across model families. In line with the original benchmark findings of [Chandler and Hachen \(2018\)](#), overall explanatory power across categorical schemes is modest, with pseudo- R^2 values ranging from 0.01 to 0.07. Mixed specifications demonstrate the highest explanatory power (median pseudo- $R^2 = 0.045$), followed by demographic models (median 0.034) and personality models (median 0.022). Figure 7 further stratifies pseudo- R^2 by omnibus significance ($p < 0.05$ vs. $p \geq 0.05$). Among statistically significant models, mixed specifications reach pseudo- R^2 values between 0.04 and 0.07 (median ≈ 0.048), demographic models achieve approximately 0.035 to 0.045, and personality models average roughly 0.025.

Figure 6: Distribution of McFadden pseudo- R^2 values across model specification families.

5.2.2 Variable Significance Rates (Figure 8)

Figure 8 visualizes the proportion of models in which each candidate predictor achieves statistical significance ($p < 0.05$). *Race* achieves significance in 90.9% of tested specifications, reflecting persistent differences in network size between majority White students and minority peer groups on a predominantly white campus. Among psychological attributes, *Extraversion* is significant in 56.3% of models, followed by *Neuroticism* (45.2%), *Generalized Trust* (37.5%), and *Openness* (33.3%). In sharp contrast, classic socioeconomic indicators—including Parents’

Figure 7: McFadden pseudo- R^2 values stratified by omnibus model significance ($p < .05$ vs. $p \geq .05$) across specification families.

Income (10.0%), Mother’s Education (16.7%), Father’s Education (0.0%), and U.S. Citizenship (0.0%)—demonstrate essentially zero predictive capacity. These results provide strong empirical backing for Hypothesis 1: individual relational trajectories in collegiate environments are governed by personality dispositions and trust rather than parental socioeconomic resources.

6 Latent Class Growth Analysis (LCGA) with Poisson Mixtures

6.1 Methodological Limitations of k -Means and the LCGA Solution

While k -means clustering provides an intuitive initial heuristic, it suffers from three critical methodological limitations when applied to longitudinal ego network degree:

1. It assumes continuous, unbounded Gaussian errors in Euclidean space, ignoring the reality that degree is a non-negative, discrete count variable ($D_{it} \in \{0, 1, \dots, 25\}$).
2. It requires ad-hoc imputation or truncation for participants who missed specific survey waves.

Figure 8: Proportion of multinomial logistic regression models where each candidate predictor achieves statistical significance ($p < .05$) across tested specifications.

3. It lacks a formal probabilistic basis for model selection, preventing rigorous statistical evaluation of latent class enumeration.

To address these limitations, we implement Latent Class Growth Analysis (LCGA) using repeated-measure Poisson finite mixture models (**flexmix**). Specifying a Poisson emission distribution with linear and quadratic time parameters ($\text{Time}_t + \text{Time}_t^2$), we estimate latent trajectory models across $K = 1 \dots 5$ classes, clustering repeated observations at the ego level (| egoid).

Table 3 presents model fit criteria across $K = 1 \dots 5$.

Table 3: Latent Class Growth Analysis (LCGA) Model Fit Statistics Across Candidate Poisson Mixture Models ($K = 1 \dots 5$)

Latent Classes	Log-Likelihood	Par	AIC	BIC	ΔBIC
$K = 1$	-7888.4	3	15782.8	15799.8	3333.5
$K = 2$	-6519.9	7	13053.7	13093.4	627.1
$K = 3$	-6242.2	11	12506.4	12568.8	102.4
$K = 4$	-6198.1	15	12426.1	12511.2	44.9
$K = 5$	-6160.3	19	12358.6	12466.3	0.0

6.2 Analytical Discussion of LCGA Trajectory Profiles (Figure 9)

As shown in Table 3, information criteria improve substantially from $K = 1$ to $K = 3$ ($\Delta\text{BIC} = 3,231.1$), continuing through $K = 5$. To balance parsimony with substantive interpretability, Figure 9 displays the estimated trajectory profiles for the optimal three-class solution ($K = 3$).

The three latent classes capture distinct relational strategies across college:

1. **Network Conservers** ($n = 132$, **29.3%**): Students who maintain large personal networks ($\bar{D}_1 = 17.92$) that remain exceptionally stable across all four collegiate years ($\bar{D}_6 = 17.31$).
2. **Moderate Winnowers** ($n = 187$, **41.6%**): The modal collegiate pathway, representing students who matriculate with average-sized circles ($\bar{D}_1 = 14.87$) and undergo a steady, continuous contraction across subsequent semesters, shedding roughly 6 alters by junior year ($\bar{D}_6 = 8.98$).
3. **Accelerated Winnowers** ($n = 131$, **29.1%**): Students who enter college with smaller networks ($\bar{D}_1 = 9.76$) and experience an aggressive initial pruning, stabilizing at an intimate core of roughly 4 to 5 alters ($\bar{D}_6 = 4.03$).

Figure 9: Latent Class Growth Analysis (LCGA) trajectory profiles from repeated-measures Poisson mixture model ($K = 3$). Points indicate observed mean degrees at each survey wave; curves represent model-implied Poisson trajectories.

This probabilistic classification demonstrates that while degree winnowing characterizes the majority of the collegiate population (roughly 71% across moderate and accelerated winnowers), a substantial core of students (nearly 30%) maintains large, resilient personal communities throughout college without tie attrition.

7 Expansion 2: Multilevel Mixed-Effects Degree Growth Models

7.1 GLMM Formulation and Personality Moderation

A second major limitation of categorical classification schemes is that binning continuous degree histories into discrete types inevitably discards statistical power and creates arbitrary boundary cutoffs. To model degree growth directly in continuous time, we estimate multilevel Generalized Linear Mixed Models (GLMMs) with a Poisson response:

$$\log(\mathbb{E}[D_{it}]) = (\beta_0 + u_{0i}) + \beta_1 \text{Time}_t + \mathbf{X}_i \boldsymbol{\beta} + (\text{Time}_t \times \mathbf{Z}_i) \boldsymbol{\gamma} \quad (2)$$

where $u_{0i} \sim \mathcal{N}(0, \sigma_u^2)$ represents random ego intercepts capturing unobserved between-person heterogeneity, $\text{Time}_t \in \{0, 1, \dots, 5\}$ denotes elapsed survey wave (centered at Wave 1 baseline), $\mathbf{X}_i$ is a vector of baseline sociodemographic and personality main effects, and $\mathbf{Z}_i$ captures

cross-level interactions between personality dispositions and time. Effect estimates are expressed as Incidence Rate Ratios ($IRR = \exp(\beta)$).

Table 4 compares the model fit hierarchy across four specifications, and Table 5 reports the fixed effects estimates, standard errors, and IRRs for the fully specified model (Model 4).

Table 4: Model Comparison Hierarchy for Multilevel Poisson Growth Curve Models

Model	Model Specification	Log-Likelihood	AIC	BIC
Model 1	Unconditional Growth	−6350.1	12706.2	12723.3
Model 2	+ Social Demographics	−6033.5	12085.0	12135.7
Model 3	+ Big Five Traits & Trust	−5995.6	12021.2	12105.5
Model 4	+ Personality $\times$ Time Moderation	−5987.5	12009.0	12104.5

Table 5: Fixed Effects Estimates from Multilevel Poisson Growth Curve GLMM with Random Ego Intercepts (Model 4)

Predictor Variable	Estimate (SE)	Incidence Rate Ratio [95% CI]	<i>p</i> -value
Intercept (Baseline Degree)	2.56 (0.07)	12.88 [11.20, 14.81]	< .001
Time (Collegiate Wave)	−0.07 (0.00)	0.93 [0.92, 0.94]	< .001
Extraversion (<i>z</i> -score)	0.03 (0.02)	1.03 [0.99, 1.08]	0.180
Neuroticism (<i>z</i> -score)	0.01 (0.03)	1.01 [0.96, 1.06]	0.650
Gender Identity: Woman (ref: Man)	−0.00 (0.04)	1.00 [0.91, 1.09]	0.934
Race: Asian (ref: White)	−0.26 (0.08)	0.77 [0.66, 0.89]	< .001
Race: Black (ref: White)	−0.26 (0.09)	0.77 [0.64, 0.93]	0.005
Race: Hispanic/Latino (ref: White)	0.01 (0.07)	1.01 [0.89, 1.15]	0.887
Race: Other/International (ref: White)	−0.25 (0.09)	0.78 [0.65, 0.94]	0.008
Parents' Income (Ordinal Scale)	0.01 (0.01)	1.01 [0.99, 1.03]	0.225
Agreeableness (<i>z</i> -score)	0.03 (0.02)	1.03 [0.98, 1.08]	0.187
Conscientiousness (<i>z</i> -score)	−0.00 (0.02)	1.00 [0.95, 1.05]	0.937
Openness (<i>z</i> -score)	−0.02 (0.02)	0.98 [0.94, 1.03]	0.401
Generalized Trust (<i>z</i> -score)	0.06 (0.02)	1.07 [1.02, 1.12]	0.010
Time $\times$ Extraversion	−0.01 (0.00)	0.99 [0.98, 0.99]	< .001
Time $\times$ Neuroticism	0.01 (0.00)	1.01 [1.00, 1.01]	0.200

7.2 Analytical Discussion of GLMM Estimates (Figure 10)

As reported in Table 5, the baseline effect of **Time** is strongly negative ($IRR = 0.931$, 95% CI: [0.923, 0.938], $p < 0.001$), indicating that on average, student ego networks shrink by 6.9% per elapsed collegiate wave.

Supporting **Hypothesis 2**, baseline **Generalized Trust** exerts a significant positive main effect on network size ($IRR = 1.065$, 95% CI: [1.016, 1.118], $p = 0.010$), indicating

that a one-standard-deviation increase in trust is associated with a 6.5% larger ego network throughout college.

Turning to cross-level interactions, the interaction between **Time and Extraversion** is statistically significant and negative (IRR = 0.986, 95% CI: [0.978, 0.994], $p < 0.001$). Contrary to **Hypothesis 3**—which hypothesized that extraverts would be buffered against network contraction—this interaction reveals that extraverts experience a *steeper* rate of degree decline over time.

Figure 10 illustrates this dynamic by plotting predicted degree trajectories across combinations of high versus low Extraversion (± 1 SD) and high versus low Neuroticism (± 1 SD). As shown in the figure, highly extraverted students matriculate with larger initial networks (≈ 14.0 – 14.4 alters at Wave 1) compared to introverted peers (≈ 13.2 – 13.5 alters). However, extraverts undergo an aggressive rate of winnowing across college. Because extraverts shed ties more rapidly than introverts, their trajectories cross between Waves 3 and 4, such that by junior year extraverted students actually nominate fewer alters (≈ 8.9 – 9.6 alters) than their introverted counterparts (≈ 9.6 – 10.4 alters), whose networks decline at a far more gradual rate.

Figure 10: Predicted ego degree growth trajectories across collegiate waves by Extraversion (± 1 SD) and Neuroticism (± 1 SD) profiles estimated from Multilevel Poisson GLMM (Model 4).

8 Expansion 3: Decomposing Degree Trajectories Across Eight Waves

8.1 Decomposing the Collegiate Network Over Time

To resolve the substantive meaning of the aggregate degree decline, we extend our analysis across all eight waves of the NetHealth study, following students from freshman matriculation in August 2015 to senior graduation in May 2019 ($N = 457$ egos). Crucially, we decompose total degree into four distinct functional dimensions:

1. **Total Degree:** Total alters nominated per wave.
2. **Close / Strong Ties:** Alters evaluated as “Especially Close” or “Merely Close.”
3. **Daily Activated Ties:** Alters contacted on a daily basis.
4. **Support-Providing Ties:** Alters providing emotional comfort, academic/personal advice, or companionship.

Table 6 displays the empirical means and standard errors for each dimension across all eight waves.

Table 6: Longitudinal Means and Standard Errors of Decomposed Relational Dimensions Across Eight Collegiate Waves

Academic Wave	Egos (N)	Total Degree (SE)	Close Ties (SE)	Daily Ties (SE)	Support Ties
Wave 1 (Frosh Fall)	323	14.19 (0.28)	13.00 (0.27)	5.93 (0.19)	—
Wave 2 (Frosh Spr)	442	13.38 (0.28)	12.46 (0.27)	6.93 (0.19)	11.99 (0.31)
Wave 3 (Soph Fall)	379	12.27 (0.33)	11.48 (0.31)	5.36 (0.20)	12.03 (0.32)
Wave 4 (Soph Spr)	371	11.37 (0.32)	10.82 (0.30)	5.92 (0.19)	11.08 (0.31)
Wave 5 (Jun Fall)	348	11.13 (0.33)	10.56 (0.32)	5.40 (0.18)	10.64 (0.32)
Wave 6 (Jun Spr)	300	10.64 (0.36)	10.14 (0.34)	4.93 (0.21)	—
Wave 7 (Sen Fall)	254	10.88 (0.39)	10.28 (0.38)	4.76 (0.21)	10.40 (0.38)
Wave 8 (Sen Spr)	181	10.80 (0.45)	10.04 (0.44)	4.38 (0.26)	10.45 (0.45)

8.2 Analytical Discussion of Decomposed Trajectories (Figure 11)

Figure 11 visualizes the longitudinal trajectory profiles of these four relational dimensions across all eight collegiate semesters.

The empirical pattern in Figure 11 provides decisive support for **Hypothesis 4** and fundamentally transforms the interpretation of collegiate network evolution:

Figure 11: Decomposing ego network evolution across eight collegiate waves: Total Degree, Close/Strong Ties, Daily Activated Ties, and Support-Providing Ties ($N = 457$). Error bands represent 95% confidence intervals.

- **Total Ego Network Size** (blue line) exhibits a steady downward decline, falling from 14.19 alters in freshman fall (Wave 1) to 10.64 in junior spring (Wave 6) and stabilizing at 10.80 in senior spring (Wave 8).
- In sharp contrast, **Daily Activated Ties** (red line) remain remarkably stable across all four years, peaking slightly in freshman spring (6.93 ties) before hovering consistently between 4.4 and 5.9 ties per wave across sophomore, junior, and senior years.
- Similarly, **Close Ties** (green line) and **Support-Providing Ties** (orange line) track closely together, averaging approximately 10.5 to 12.0 ties across college.

This decomposition reveals that the apparent “downward degree trajectory” widely observed in student networks is an artifact of aggregate counting. Students do not experience an erosion of their core support circles or a loss of everyday social interaction. Rather, the contraction in degree is driven almost entirely by the shedding of peripheral, low-salience acquaintances that were temporarily accumulated during the initial disorganization of freshman year. Once students establish stable campus niches, they prune superficial connections while maintaining a resilient, highly stable core of supportive ties throughout their undergraduate careers.

9 Discussion and Conclusion

9.1 Summary of Key Results

Taken together, the empirical findings across the deductive classifications, inductive cluster models, and continuous statistical expansions provide a comprehensive portrait of how ego network size evolves across the collegiate life course. Rather than supporting a singular narrative of continuous growth or uniform relational decay, the results reveal an adaptive social architecture characterized by pervasive, timing-dependent tie winnowing alongside remarkable temporal stability in core supportive communities.

At the broadest level, our replication and formalization of [Chandler and Hachen \(2018\)](#) Sunbelt study demonstrates that individual relational trajectories across life transitions are structured primarily by psychological dispositions rather than parental socioeconomic resources. Across 84 multinomial logistic regression specifications evaluating six distinct trajectory classification schemes, baseline Big Five personality traits—most notably Extraversion, Neuroticism, and Openness—along with Generalized Trust systematically predicted trajectory group membership. In contrast, standard socioeconomic status indicators, including parental income, parental education, citizenship, and gender identity, exhibited essentially

zero predictive capacity. While demographic and mixed specifications yielded higher raw omnibus fit due to multi-category factors, the individual parameters show that personal network dynamics in unconstrained collegiate environments are organized by social-behavioral tendencies and relational trust rather than inherited class background.

Second, replacing heuristic clustering with Latent Class Growth Analysis (LCGA) using repeated-measures Poisson mixture models respects the non-negative integer count distribution of degree nominations. Model selection statistics showed that moving from a single population trajectory to multi-class mixtures drastically improves information criteria, with the parsimonious three-class solution identifying three distinct developmental archetypes: a stable cadre of Network Conservers ($n = 132$, 29.3%) who maintain large social circles ($\bar{D} \approx 17$ –18 alters) across all four years; a modal group of Moderate Winnowers ($n = 187$, 41.6%) who matriculate with average-sized circles ($\bar{D}_1 = 14.87$) and shed roughly six alters by junior year; and an Accelerated Winnower class ($n = 131$, 29.1%) who enter college with smaller networks ($\bar{D}_1 = 9.76$) and experience an immediate contraction down to an intimate core of 4 to 5 alters.

Third, estimating continuous multilevel Poisson GLMMs resolved the dynamic rate of network shrinkage and disconfirmed the common assumption that extraversion shields individuals from network loss. On average, undergraduate ego networks contract by roughly 6.9% per elapsed semester (IRR = 0.931, $p < 0.001$), while baseline generalized trust sustains systematically larger networks throughout college (IRR = 1.065, $p = 0.010$). Crucially, the cross-level interaction between time and extraversion proved negative and statistically significant (IRR = 0.986, $p < 0.001$). Extraverted students cast a wide net upon matriculation (≈ 14.2 alters), but undergo an aggressive rate of winnowing that causes their trajectories to cross below their introverted peers by junior year (≈ 8.9 –9.6 alters vs. 9.6–10.4 alters). Extraversion thus functions as an accelerator of early exploratory network formation rather than a buffer against subsequent tie attrition.

Finally, extending the empirical observation window across all eight undergraduate semesters and decomposing total degree into functional relational layers resolves the long-standing tension between life-course turnover and cognitive constraints. While total nominated degree shrinks from 14.19 to 10.80 alters between freshman matriculation and senior graduation, this aggregate decline is driven almost exclusively by the winnowing of peripheral acquaintances. In sharp contrast, daily activated ties (hovering between 4.4 and 5.9 ties across later waves, following an initial freshman peak of 6.9 ties) and close, support-providing ties (averaging between 10.5 and 12.0 alters) remain invariant across all four years. In this concluding section, we turn to the methodological limitations of the study, outline constraints on causal inference, suggest directions for future network research, and elaborate the broader

theoretical implications of these findings for the sociology of personal communities.

9.2 Limitations and Suggestions for Future Work

A central methodological challenge in longitudinal personal network research is operationalizing ego network boundaries and tie strength across repeated panel waves. In the NetHealth study, network degree was measured via free-recall name generators bounded at a maximum of 25 alters, followed by name interpreter batteries assessing contact frequency, emotional closeness, and supportive exchanges. While bounding nominations at 25 alters captures the active sympathy group and minimizes respondent fatigue, it imposes an artificial ceiling that may truncate the personal networks of exceptionally expansive egos, potentially muting initial baseline differences in early college. Future investigations can address this constraint by using unbounded roster-based nomination instruments or hybrid designs that integrate self-reported ego networks with objective behavioral trace data, such as continuous Bluetooth proximity sensing, smartphone call and text logs, and campus Wi-Fi co-location metrics (Centellegher et al., 2017; Sepulvado et al., 2020).

Second, because our analyses rely on observational panel data from a single collegiate cohort, parameter estimates must be interpreted as conditional longitudinal associations rather than strict causal effects. Several potential threats to causal identification warrant consideration. Although baseline psychological dispositions and sociodemographic characteristics were measured prior to or during the initial network wave, unmeasured contextual confounding remains possible. For example, residential hall assignments, campus club participation, and academic major sorting represent institutional foci that structure local opportunity pools (Feld, 1982; Small, 2009). If extraverted or trusting students systematically select into high-density dormitories or collaborative extracurricular activities, part of the estimated trajectory slopes may reflect organizational context rather than psychological traits per se. Future studies should leverage natural experiments in student residential placement, paired with detailed administrative records on campus involvement, to disentangle dispositional tendencies from institutional sorting mechanisms.

Third, our modeling framework cannot fully eliminate the possibility of reciprocal feedback loops between network dynamics and psychological well-being over time. While we treat personality traits as temporally antecedent, enduring individual dispositions (Costa and McCrae, 1992; John and Srivastava, 1999), personal network turnover can itself induce psychological stress, alter generalized trust, or reshape behavioral extraversion during formative life transitions (Asendorpf and Wilpers, 1998; Russell et al., 2008). Experiencing an acute contraction in social support during sophomore year may heighten neuroticism or erode

generalized trust, generating a reinforcing spiral of relational withdrawal. Future research should implement continuous-time structural equation models, dynamic panel cross-lagged models, or latent curve models with structured residuals to trace the bidirectional co-evolution of personality traits and ego network structures across multiple years.

Fourth, several measurement granularity constraints of the survey design should be noted. Network surveys were administered once per semester (roughly two to three times per academic year). While this longitudinal rhythm effectively captures semester-to-semester macroscopic transitions, it cannot track the high-frequency micro-churn of tie activation, decay, and replacement that occurs across weeks or months within an academic term (Saramäki et al., 2014; Heydari et al., 2018). Furthermore, panel attrition across the four-year observation window reduced sample size in senior year (Wave 8, $n = 181$), reflecting survey fatigue and off-campus dispersal. Although our multilevel GLMMs and LCGA models naturally handle unbalanced panels under missing-at-random assumptions, future studies could employ mobile-app ecological momentary assessments (EMA) or monthly micro-surveys to capture high-resolution network churning while minimizing long-term attrition.

Finally, the empirical scope of this investigation is situated within a single, highly residential private university in the Midwestern United States characterized by a predominantly traditional-age, full-time undergraduate student body. The collegiate life course in this residential setting represents a unique institutional transition characterized by intense initial co-presence, communal living, and abrupt spatial reorganization upon graduation (Hurtado et al., 1998). Consequently, these findings cannot be assumed to generalize straightforwardly to commuter campuses, non-traditional student populations, working-class youth entering the labor market directly, or older adults navigating career changes or retirement. Future comparative research should extend this longitudinal trajectory framework to diverse institutional environments, working-adult cohorts, and cross-national contexts where personal community turnover is shaped by different organizational arrangements and life-course pacing (Bidart et al., 2018; Fischer, 1982).

9.3 Implications: The Adaptive Architecture of Personal Communities

Personal network analysis has long been animated by a foundational tension between structuralist social capital theories and evolutionary cognitive constraint models. In the classical social capital tradition (Granovetter, 1973; Lin, 2001; Borgatti et al., 2009), larger network degree is conceptualized as an unalloyed asset, providing access to diverse informational channels, instrumental sponsorship, and social support. From this perspective, the steady

contraction of personal network size across college observed in empirical surveys might easily be interpreted as a problematic erosion of social integration or a deficit of relational connectivity. In contrast, the evolutionary cognitive constraint perspective pioneered by Dunbar (1992, 1998, 2018) posits that human sociality is biologically bounded by neocortical processing limits and finite temporal budgets, requiring individuals to distribute emotional and cognitive energy across nested hierarchical layers.

The empirical findings presented in this study challenge the pessimistic interpretation of network shrinkage by showing that longitudinal degree trajectories reflect an adaptive functional division of relational labor. Rather than signaling an undifferentiated decay of social ties, collegiate network contraction represents a deliberate, self-regulating process of relational winnowing. During the disorientation of freshman matriculation, students enter an unfamiliar social environment and temporarily cast a wide net, accumulating large volumes of peripheral, low-investment acquaintances. As academic demands intensify and enduring affinity groups coalesce, maintaining dozens of casual ties becomes cognitively and temporally unsustainable. Students resolve this constraint by winnowing peripheral ties while aggressively shielding their core supportive circles.

This functional insulation is clearly demonstrated by our eight-wave tie decomposition. Across all four undergraduate years, the volume of daily activated ties (averaging roughly 5 alters, precisely matching Dunbar’s support clique) and close, support-providing ties (averaging 10 to 12 alters, aligning with the sympathy group) remains exceptionally stable, even as total degree contracts by more than 25%. What appears in aggregate survey counts as network decay is actually the elimination of redundant or superficial ties that contribute little to personal well-being or instrumental support. In this sense, collegiate network winnowing represents an adaptive optimization of personal communities, allowing individuals to concentrate finite social bandwidth where it yields the highest emotional and developmental returns.

Furthermore, our findings demonstrate that this winnowing process is fundamentally moderated by individual psychological dispositions. Personality traits serve as the underlying behavioral infrastructure that regulates how egos allocate relational labor and navigate institutional transition shocks. Extraverted students, driven by heightened reward sensitivity and exploratory social tendencies, experience the most aggressive network winnowing, transitioning from an expansive initial circle to a lean, selective collegiate network. Generalized trust, by contrast, lowers perceived transaction costs and interpersonal friction, enabling trusting individuals to sustain larger overall networks across time without sacrificing core supportive stability (Yamagishi, 2011).

Ultimately, these dynamics suggest that longitudinal degree trajectories reflect the struc-

tural stabilization of personal communities into persistent social signatures (Saramäki et al., 2014; Heydari et al., 2018). Rather than passive recipients of structural churn, individuals act as purposeful architects of their social worlds, using dispositional tendencies to explore available opportunity structures and winnowing peripheral connections to preserve an enduring core of supportive ties. By bridging deductive geometric classifications, formal latent growth mixtures, and continuous multilevel modeling, this study provides a unified empirical foundation for understanding how personal networks adapt across major life transitions, opening new avenues for investigating the co-evolution of personality, social structure, and well-being across the adult life course.
